# Block 23 — Comparator Circuits

## Learning objectives

After this 90-minute block, you will be able to

- explain what a **comparator** is and how it differs from an operational amplifier used in closed-loop (linear) operation:
  1. intended for **switching**, not linear amplification
  2. designed to operate at the output limits (**saturation**) rather than keeping the differential input near zero
  3. commonly used with **positive feedback** when hysteresis is desired (Schmitt trigger)
- interpret the comparator's inputs and differential voltage
- describe and distinguish **open-collector** vs. **push-pull** comparator outputs and state when a **pull-up resistor** is required.
- predict the output state of a comparator from the sign of  $(u_{\text{d}})$  and the available saturation levels  $(U_{\text{sat,min}})$ ,  $(U_{\text{sat,max}})$ .
- explain why noise at the switching point can cause rapid toggling and how **hysteresis** prevents this.
- analyze a **non-inverting Schmitt trigger** and compute its switching thresholds
  1. upper threshold  $(U_{\text{sh,u}})$
  2. lower threshold  $(U_{\text{sh,l}})$

## Preparation at Home

Well, again

- read through the present chapter and write down anything you did not understand.
- Also here, there are some clips for more clarification under 'Embedded resources' (check the text above/below, sometimes only part of the clip is interesting).

For checking your understanding please do the following exercises:

- ...

## 90-minute plan

1. Warm-up (5-10 min):
  1. Recall: op-amp with negative feedback vs. no feedback.
  2. Live demo or simulation: sweep  $(u_{\text{p}})$  across  $(u_{\text{m}})$  and observe comparator switching.
2. Core concepts (45-50 min):
  1. Comparator basics: inputs, differential voltage  $(u_{\text{d}}=u_{\text{p}}-u_{\text{m}})$ , saturation behavior.
  2. Output stages: open-collector vs. push-pull; role of pull-up resistor.
  3. Noise problem at the switching point.

4. Non-inverting Schmitt trigger:
  1. positive feedback
  2. hysteresis
  3. derivation and interpretation of  $(U_{\text{sh,u}})$  and  $(U_{\text{sh,l}})$ .
3. Applications (15–20 min):
  1. Bang-bang control
  2. De-noising / signal conditioning
  3. Comparator as basic ADC element
4. Wrap-up (5 min):
  1. Key takeaways
  2. Typical mistakes and outlook to further applications

## Conceptual overview

1. A **comparator** is the “switching cousin” of the op-amp: it does not try to keep  $(u_{\text{d}} \approx 0)$  with negative feedback. Instead, it reports the **sign** of  $(u_{\text{d}} = u_{\text{p}} - u_{\text{m}})$  by saturating its output to one of two extreme levels.
2. The output is therefore **binary-like** (low/high), set by the supply rails via  $(U_{\text{sat,min}})$  and  $(U_{\text{sat,max}})$ . The exact “high” behavior depends on the output stage:
  1. **Push-pull** drives both levels.
  2. **Open-collector** can reliably pull low, but needs a **pull-up resistor** to produce a defined high level.
3. The critical moment is around  $(u_{\text{d}} = 0)$ . Real signals are noisy, so a plain comparator can **toggle rapidly** (“chatter”) when the input hovers near the threshold.
4. A **Schmitt trigger** fixes this by adding **positive feedback**, creating two thresholds:
  1. one threshold for rising input (upper threshold)
  2. another for falling input (lower threshold)

This separation is **hysteresis**.

1. In the non-inverting Schmitt trigger, the thresholds scale with the feedback ratio  $(R_1/R_2)$  and the current output saturation level. Bigger feedback (larger  $(R_1/R_2)$ ) → wider hysteresis → better noise immunity, but less sensitivity.
2. Many practical “make a clean digital signal” tasks boil down to comparator ideas: thresholding (ADC intuition), de-noising/debouncing, and bang-bang control.

## Core content

### Comparator

Up to now we focussed on operational amplifier, which is only usable in a closed-loop setup. However, it also as a “special brother”, the **comparator**.

The differences form the comparator in contrast to the operational amplifier are:

1. It is **only used in positive feedback**. It should never be used in negative feedback.

2. It is optimized for **fast switching**
3. It only outputs **in saturation**, which means it only has two possible outputs, see details below.

The symbol is related to the op-amps triangular shape - often the exact same symbol is used.

We again have two inputs: The non-inverting input  $u_{\text{p}}$  and the inverting input  $u_{\text{m}}$ . They result in the differential voltage  $u_{\text{d}} = u_{\text{p}} - u_{\text{m}}$ .

So, but what is the output, now? For this, it helps to have a look onto the simulation below.

There are two types of comparators:

1. **comparators with open-collector output:**

This type outputs the minimum value, when the non-inverted input is bigger than the inverted one.

Otherwise, the output is **high-ohmic** or **undefined**.

This is sometimes shown by a diamond shape  $\diamond$  on the output.

For these type, a **pull-up resistor** is needed to have a readable output in case of  $u_{\text{d}} > 0$ .

$$u_{\text{O,OC}} = \begin{cases} \text{undefined} & \text{for } u_{\text{d}} > 0 \\ U_{\text{sat, min}} & \text{for } u_{\text{d}} < 0 \end{cases}$$

2. **comparators with push-pull output:**

This type outputs the minimum value, when the non-inverted input is bigger than the inverted one.

Otherwise, it outputs the maximum value.

$$u_{\text{O,PP}} = \begin{cases} U_{\text{sat, max}} & \text{for } u_{\text{d}} > 0 \\ U_{\text{sat, min}} & \text{for } u_{\text{d}} < 0 \end{cases}$$

Similar to the operational amplifier, the situation  $u_{\text{d}} = 0$  is important.

This time,  $u_{\text{d}} = 0$  is not automatically reached, but it is the “turning point” for changing the output value.

The values of the output voltages  $U_{\text{sat, min}}$  (and  $U_{\text{sat, max}}$ , when defined) are given by the voltage supply of the comparator,

In the first simulation they are set unipolar to  $U_{\text{sat, min}} = 0 \text{ V}$  and  $U_{\text{sat, max}} = 5 \text{ V}$ .

## Non-inverting Schmitt Trigger

Based on the comparator, we can try to setup a “op-amp like” circuitry. However, we have to take

care, that we use a positive feedback.

The most important circuit is similar to the inverting amplifier, but with positive feedback is it the **non-inverting Schmitt trigger**.

The **golden rules** ( $R_{in}=0$ ,  $R_{out} \rightarrow \infty$ ,  $A_{D} \rightarrow \infty$ ) also apply here.

Therefore, the currents through the resistors  $R_1$  and  $R_2$  are the same:  $i_1 = i_2$  (given, that  $R_{out} \rightarrow \infty$ ).

$$u_{D}=0 \quad \rightarrow \quad u_{O} \text{ \textit{changes its state} }$$

At the “turning point” with  $u_{D}=0$ , the input and output voltages are equal to the voltages over the resistances.

However, the signs have to be considered (when  $u_{O}$  is positive,  $u_i$  has to be negative for  $u_{D}=0$ ):  $u_1 = -u_i \quad \wedge \quad u_2 = u_{O}$

Then, the currents  $i_1$  and  $i_2$  are given by  $i_1 = -\frac{u_1}{R_1} \quad \wedge \quad i_2 = \frac{u_{O}}{R_2}$

And therefore, this “turning point” is given by  $u_1 = -\frac{R_1}{R_2} \cdot u_{O}$

These “turning points” are called **threshold**.

The upper threshold  $U_{sh,u}$  and the lower threshold  $U_{sh,l}$  are given by  $\boxed{U_{sh,u} = +\frac{R_1}{R_2} \cdot u_{O} \quad \wedge \quad U_{sh,l} = -\frac{R_1}{R_2} \cdot u_{O} }$

The shown “switching effect” is called **hysteresis**.

The curve is called **hysteresis loop** and shows the switching at the upper and lower threshold.

## Applications

### Bang-Bang Control

See [Bang-bang\\_control](#)

### De-Noise

Real analog signals are often corrupted by noise.

When such a signal is fed directly into a comparator, small noise amplitudes around the threshold can cause rapid switching of the output (chatter).

The Schmitt trigger solves this problem by its two distinct thresholds  $(U_{\text{sh,u}})$  and  $(U_{\text{sh,l}})$ .

As long as the input signal remains between these two values, the output state does not change.

This makes comparators with hysteresis ideal for:

- cleaning up slowly varying or noisy sensor signals,
- debouncing mechanical switches,
- converting noisy analog waveforms into clean digital signals.

## Analog-to-Digital Converter (ADC)

At its core, every analog-to-digital converter contains at least one **comparator**.

A comparator performs a **binary decision**:

Is the input voltage larger or smaller than a given reference?

In the simplest case (1-bit ADC):

- one comparator compares  $(u_{\text{I}})$  with a reference voltage  $(U_{\text{ref}})$ ,
- the output represents a single digital bit.

More complex ADCs like the flash ADC (shown in the simulation below) use multiple comparators or reuse one comparator repeatedly with different reference values.

Thus, understanding comparator behavior is fundamental for understanding how analog information is converted into digital form.

## Common pitfalls

- **Treating a comparator like a linear op-amp:** assuming the output follows a linear gain law  $(u_{\text{O}} = A_{\text{D}} \cdot u_{\text{d}})$ . In reality, the output almost always saturates at  $(U_{\text{sat,min}})$  or  $(U_{\text{sat,max}})$ .
- **Using negative-feedback intuition:** expecting the circuit to automatically enforce  $(u_{\text{d}} = 0)$ . Without negative feedback,  $(u_{\text{d}} = 0)$  is only the *switching boundary*, not an operating point.
- **Mixing up inputs:** confusing the non-inverting input  $(u_{\text{p}})$  and inverting input  $(u_{\text{m}})$ , which leads to predicting the wrong output polarity.
- **Ignoring the output stage type:**
  1. forgetting that an **open-collector** comparator cannot actively drive a high level,
  2. omitting the required **pull-up resistor**, resulting in an undefined/high-ohmic output.
- **Forgetting saturation limits:** assuming ideal logic levels, while real comparators are limited by their supply voltages  $(U_{\text{sat,min}})$ ,  $(U_{\text{sat,max}})$ .
- **No hysteresis for noisy signals:** using a plain comparator where a Schmitt trigger is required, leading to output chatter when  $(u_{\text{I}})$  fluctuates near the threshold.
- **Sign errors in Schmitt-trigger thresholds:** losing track of the sign of  $(u_{\text{O}})$  when deriving or applying

$$\llbracket U_{\text{sh,u}} = +\frac{R_1}{R_2} u_{\text{O}}, \quad U_{\text{sh,l}} = -\frac{R_1}{R_2} u_{\text{O}}. \rrbracket$$

## Exercises

### Conceptual checks

1. Explain in one or two sentences why a comparator is normally operated without negative feedback.
2. What information about the input signal does the comparator output represent when  $(u_{\text{O}})$  is in saturation?
3. Why is  $(u_{\text{d}} = 0)$  a special point for a comparator, even though it is not a stable operating

point?
